Abstract

Multi-pixel photodiodes operating in a limited Geiger mode will be used for photoreadout of scintillator counters in underground cosmic ray experiment EMMA. Main parameters of photodiodes and the performance of EMMA scintillator counters are presented.

1 Introduction

The goal of the EMMA experiment is to study the chemical composition of the primary cosmic rays around the “knee” region at the energy of about 3×10^{15} eV by measuring the multiplicity, lateral distribution and arrival direction of the underground cosmic ray muons. The EMMA detector will be constructed in the Pyhäsalmi mine, Finland [1]. It consists of drift chambers and plastic scintillator detectors and has the total area of ~ 135 m² at the depth of 85 m (about 240 meters of water equivalent).

In total, about 1600 scintillator counters, 122×122 mm² and 3 cm thick, are arranged in 4×4 arrays, each of 16 counters, which form individual detectors of 50 cm \times 50 cm in cross section. Scintillator counters use wavelength shifting (WLS) fiber readout. Photosensors, Geiger-mode multi-pixel avalanche photodiodes, are mounted inside the counters. The set-up employing such photosensors is a unique device designed for the cosmic-ray induced underground muon detection.

2 Parameters of MRS APD's

Detailed description of multi-pixel avalanche photodiodes with a metal–resistor–semiconductor layer structure operating in a limited Geiger mode (hereafter referred to as MRS APD's or MRS photodiodes) can be found in Refs. [2, 3]. Such a photosensor consists of many independent sensitive pixels produced on a common p–type silicon substrate. A simplified topology of an MRS photodiode, invented and designed by the Center of Perspective Technologies and Apparatus (CPTA), Moscow, is shown in Fig. 1(a). Each pixel operates as an independent

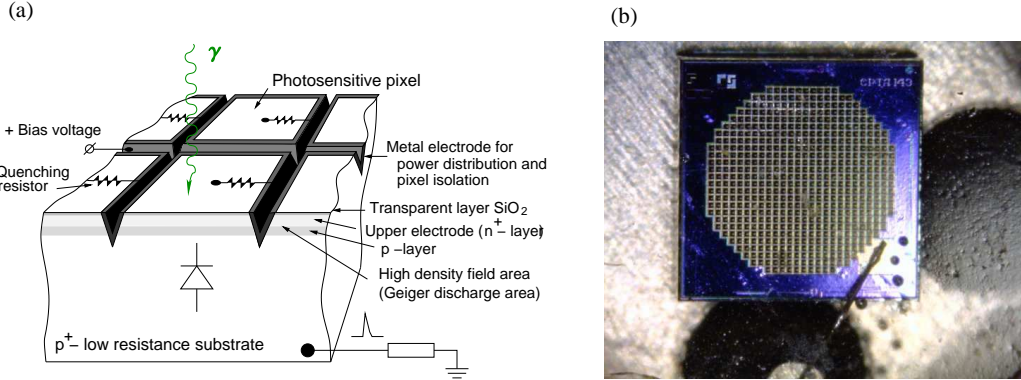

Figure 1: MRS APD: (a) schematic view of the structure; (b) photo of the sensitive area.

Geiger micro-counter with a gain of the same order as a vacuum photomultiplier. Pixels are separated by grooves filled with an optically non-transparent material to suppress an optical cross-talk. The MRS photodiodes with 556 pixels of $35 \times 35 \mu\text{m}^2$ each and total sensitive area of 1.1 mm^2 (see Fig. 1(a)) were manufactured by CPTA for the EMMA experiment. Main parameters of these MRS APD's are reviewed below.

Bias voltage. The bias voltage, V_{bias} , applied on a photodiode creates a very high electric field in a very thin layer ($\sim 1 \mu\text{m}$ p-n junction). The bias voltage is set to be above the breakdown level, V_{bd} , so that the electric field can sustain the carrier's avalanche; however there is no current through the depletion layer until the first carrier is generated. Value of overvoltage $\Delta V = V_{bias} - V_{bd}$ determines the gain, photon detection efficiency (PDE), intrinsic noise and cross-talk. Typical bias voltage of MRS APD's for EMMA detectors is around 30-32 V. We apply the overvoltage of 4 V in operating mode for tests. EMMA electronics will automatically tune the bias voltages to have the background signals in the detector roughly at the same rate for all counters.

Photon detection efficiency. The PDE was measured at room temperature with a spectrophotometer and a calibrated PMT as described in [4, 5]. Our result for PDE is about 25% for green light region (WLS fiber emission spectrum) at the operating bias voltage. The PDE values of MRS APD's in green light region is close to that of Hamamatsu MPPC's manufactured for the T2K experiment [6, 7]. We have come to this conclusion after comparative measurements between MRS APD's and MPPC's with a reference light source.

Temperature dependence. Since the breakdown voltage depends on temperature the main parameters are sensitive to ambient temperature. Parameters of an MRS photodiode (PDE and

gain) were measured inside a thermostatic box in a wide temperature interval from 10 to 38 °C. A WLS Y11 fiber excited by a blue LED was used as a light source. The stability of LED light was measured to be better than 0.1 %/°C. The results of the measurements are shown in Fig. 2. The MRS APD gain decreases with temperature as -0.4 %/°C, while the PDE varies

Figure 2: The photon detection efficiency for green light ($\lambda \sim 515$ nm) and the gain of an MRS APD as a function of the temperature.

with temperature as -0.9 %/°C. The weak sensitivity of MRS APD parameters to temperature can be explained by two factors: a weak temperature dependence of the breakdown voltage and a relatively high ΔV . V_{bd} was measured in the range from 10 to 35 °C. As seen from Fig. 3, breakdown voltage shows a weak temperature dependence with a gradient of about 16 mV/°C.

Pulse shape. The pulse shape of this type of photosensor is determined by a quenching resistor which is about 20 M Ω . This value, which affects the pulse shape, was not well controlled during the production of wafers. The pulse shape of some MRS APD's has a long tail up to a few μ s, as discussed in Ref. [8]. To overcome such a problem, all MRS APD's were separated into 4 groups according to the ratio of the fast and slow (tail) components. In addition, a large quenching resistor causes the long recovery time of about 1 μ s. Since the expected counting rate in the mine, including background from the surrounding rock, will be ≤ 100 Hz per a single counter [9], the recovery time is not a problem for the EMMA experiment. On the other hand, the long recovery time allows us to avoid after-pulses in contrast to MPPC's which were designed to have

Figure 3: Temperature dependence of the breakdown voltage. The solid line shows the best fit with a gradient of 16 mV/°C.

a fast recovery time [10].

In total, about 2200 MRS photodiodes fabricated from a few different wafers were tested. About 10 % of delivered devices were rejected as defective (no signal) during preliminary tests and returned back to the manufacturer. No more dead MRS APD's were found during tests after acceptance. In order to meet the requirements of the experiment, the operating bias voltages were set so that the dark rate of each device was close to a reference value of about 1 MHz at 22 °C at a discriminator threshold of 0.5 p.e. The breakdown voltages for these MRS APD's were found to be in a wide range 25 – 31 V that determines the range of 29 – 35 V for the applied bias voltages to provide the PDE value of $\geq 20\%$ for green light.

3 EMMA counters

An EMMA scintillator counter is shown in Fig. 4(a). Polystyrene scintillator tiles ($122 \times 122 \times 30$ mm³) have been manufactured at IHEP, Protvino, Russia. Scintillating light is collected by a single Y11 (Kuraray) WLS fiber of 1 mm diameter glued into a spiral groove of 3.2 mm depth with the BC600 Bicon glue. The groove was carved by a Woodpecker engraving-milling machine which speed and cutting tools were optimized to make a clean groove to provide the good transmission of the scintillating light through the cut surfaces. This technique was developed for scintillator counters for muon detection [11] in the near neutrino detector of the long baseline neutrino experiment T2K [12]. The fiber is viewed from one end by an MRS photodiode, the other end is covered by an aluminized mylar reflector. This readout configuration allows us to

Figure 4: Photographs: (a) an individual scintillator counter with glued Y11 fiber and embedded optical connector; (b) an EMMA module comprised of 16 counters in a 4×4 assembly.

collect scintillation light uniformly over the entire scintillator. Outer surfaces of scintillators were etched by a chemical agent that resulted in the formation of a micropore deposit over the plastic surface. The thickness of the deposit ($30 - 100 \mu\text{m}$), which works as a diffuse reflector, depends on the etching time. Details can be found in Ref. [13]. Scintillators with glued WLS fibers were wrapped into an additional reflector layer of 0.1 mm thick Tyvek paper that increases a light yield by about 15%. One module is comprised of 16 scintillator counters (4×4 assembly) which are packed into a steel box of $0.5 \times 0.5 \text{ m}^2$, as shown in Fig. 4(b).

The performance of EMMA counters was tested with cosmic ray muons using a small $2 \times 2 \text{ cm}^2$ trigger counter placed at the center of a tested counter. A typical muon spectrum is shown in Fig. 5. The light yield of about 150 photoelectrons was obtained for a 6 MeV energy deposited

Figure 5: Left: the cosmic muon spectra measured by a typical counter. The light yield of 150 p.e. corresponds to the deposited energy of about 6 MeV. Right: time resolution for cosmic muons.

by cosmic muons in the 3 cm thick counter. The obtained time resolution (σ) is about 0.9 ns (see Fig. 5) and mainly determined by the slow decay time (9-12 ns) of the Y11 fiber.

EMMA counters must provide a high light yield to separate cosmic muon signals from photon background of the rock walls ($E_\gamma = 2.6$ MeV). The light yield of more than 100 p.e. per cosmic muon allows us to suppress the photon background and keep a high efficiency ($> 95\%$) for cosmic muons. The light yield distribution for about 800 counters is shown in Fig. 6. Almost all

Figure 6: The light yield distribution of manufactured EMMA counters.

manufactured counters have the light yield of more than 100 p.e. and satisfy the requirements of the experiment.

4 Conclusion

The MRS APD's manufactured for the EMMA experiment have high PDE values and show a low temperature dependence of the main parameters. The scintillator counters with WLS fiber readout and MRS APD's provide a high light yield and a good time resolution. The production of all counters will be finished in December 2009. Installation of all modules and commissioning of the detector is expected in the first half of 2010.

It is a pleasure for authors to thank the INR technicians for their excellent work on the preparation and assembly of the detectors. The work of the authors from the University of Oulu is funded by the European Union Regional Development Fund and is also supported by the Academy of Finland (Project 108991).
